ヘロト ヘヨト ヘヨト ヘヨト

Formal definition:

Let
$$S = \{1, ..., |S|\}$$
 be a finite set.

A sequence of random variables $\{X_n\}_{n\geq 0}$ with values in S, i.e., $X_n \in S$, is a discrete-time Markov process or Markov chain if

$$P(X_{n+1} = j | X_n = i, ..., X_0 = i_0) = P(X_{n+1} = j | X_n = i) \quad (1)$$

In addition, if the right hand side of the above equation does not depend on n, the Markov chain is called homogeneous.

・ ロ ト ・ 画 ト ・ 画 ト ・ 日 ト

Let us explain the definition with some simple examples.

Example 1: Nice weather model. The weather in Nice can be in one of the following three states:

$$S_1 = \text{'Sunny'};$$

 $S_2 = \text{'Cloudy'};$
 $S_3 = \text{'Rainy'}.$

・ロット (雪) ・ (日) ・ (日) ・ (日)

Discrete-time Markov Processes

There are possible 9 types of transitions between states described by matrix P.

$$P(X_{n+1} = S_3) = P(X_{n+1} = S_3 | X_n = S_1) P(X_n = S_1) + P(X_{n+1} = S_3 | X_n = S_2) P(X_n = S_2) + P(X_{n+1} = S_3 | X_n = S_3) P(X_n = S_$$

Thus, we can write

$$\pi_{n+1}=\pi_n P,$$

where

$$\pi_{n+1,i}=P[X_{n+1}=i],$$

 and

$$\pi_{n,i}=P[X_n=i].$$

◆□▶ ◆□▶ ◆三▶ ◆三▶ 三三 のへぐ

Example 2: Symmetric Random Walk on integers. Let $S = \mathbb{Z}$, $X_0 = 0$ and "toss a coin" $k \rightarrow k+1$ w.p. $\frac{1}{2}$ $k \rightarrow k-1$ w.p. $\frac{1}{2}$ $P = \begin{vmatrix} \ddots & \ddots & \ddots \\ \frac{1}{2} & 0 & \frac{1}{2} & 0 \\ 0 & \frac{1}{2} & 0 & \frac{1}{2} & 0 \\ 0 & \frac{1}{2} & 0 & \frac{1}{2} \\ 0 & \frac{1}{2} & 0 & \frac{1}{2} \\ 0 & \frac{1}{2} & 0 & \frac{1}{2} \end{vmatrix}$

▲□▶ ▲□▶ ▲□▶ ▲□▶ □ のQで

For the infinite lattice it is possible to calculate

$$P[X_t = k] = 2^{-t} \binom{t}{\frac{t+k}{2}},$$

and then using Stirling's approximation $t! \approx \sqrt{2\pi t} e^{-t} t^t$,

$$P[X_t=k]\approx \frac{2}{\sqrt{2\pi t}}e^{-\frac{k^2}{2t}}.$$

▲□▶ ▲□▶ ▲三▶ ▲三▶ 三三 のへで

Discrete-time Markov Processes

For ergodic Markov chains, the following limit exists:

$$\lim_{n\to\infty}p^{(0)}P^n=:\pi,$$

where the raw vector π is called stationary distribution.

The stationary distribution is given as a solution of the following linear system: (in the matrix form)

$$\pi P = \pi,$$

$$\pi 1 = 1,$$

(and in the element form)

$$\sum_{i=1}^{|S|} \pi_i p_{ij} = \pi_j, \quad j \in S,$$

 $\sum_{j=1}^{|S|} \pi_j = 1.$

The rate of convergence to the stationary distribution is determined by the second largest eigenvalue $\lambda_2(P)$, i.e.,

$$||\pi - p^{(0)}P^n|| \le C |\lambda_2(P)|^n.$$

We can also consider the first hitting time to set M starting from distribution u:

$$T_M = \min\{n > 0 : X_n \in M \& X_0 \sim u\}.$$

There is a nice formula to compute the expected hitting time:

$$E[T_m] = p_M^{(0)}[I - P_M]^{-1}\underline{1},$$

where P_M is the taboo probability matrix with deleted rows and columns indexed from M and $p_M^{(0)}$ is the respective "pruned" initial distribution $p^{(0)}$.

Let us present a continuous-time version of Markov chains.

Suppose a random walker on a graph with adjacency matrix A jumps after an exponentially distributed time with rate γd_i from node i, and the next node is chosen with probability a_{ij}/d_i . $(d_i = \sum_i a_{ij}$ is the degree of node i.)

The dynamics of such random walk is described by

$$\dot{\pi}(t) = -\pi(t)\gamma L,$$

where $\pi_i(t) = P[X(t) = i]$ and L = D - A is the graph Laplacian.

・ロット (雪) ・ (日) ・ (日) ・ (日)

Let H be a Hermitian operator associates with the graph.

Some examples: A – adjacency matrix or L = D - A -Laplacian.

Then, a simple way to construct a unitary operator is

$$U(t) = \exp(-iHt)$$

and the evolution of the continuous-time quantum walk is given by

$$\ket{\psi(t)} = U(t) \ket{\psi(0)}.$$

However,...

▲□▶ ▲□▶ ▲三▶ ▲三▶ - 三 - のへで

There is a "small" problem: U(t) is not local.

$$U(t)\approx I-iHt-\frac{1}{2}H^2t^2...$$

Now instead of classical coin let us toss "quantum" coin $|c\rangle$. "Head" $\leftrightarrow |0\rangle$ "Tail" $\leftrightarrow |1\rangle$

Unlike the case of the classical coin, there is a lot of freedom in the choice of modelling "quantum coin". The most used coin is the Hadamard operator

$$H = \frac{1}{\sqrt{2}} \left[\begin{array}{cc} 1 & 1 \\ 1 & -1 \end{array} \right].$$

◆□▶ ◆冊▶ ◆臣▶ ◆臣▶ ─ 臣 ─

Discrete-time coined quantum walk on integers

In the discrete-time coined quantum walk, the state is $|c\rangle |k\rangle$ and its evolution is as follows:

- 1. Apply the Hadamard operator to the coin state.
- 2. Apply the shift operator:

$$egin{aligned} S \ket{0} \ket{k} &= \ket{0} \ket{k+1}, \ S \ket{1} \ket{k} &= \ket{1} \ket{k-1}. \end{aligned}$$

3. Repeat or measure.

The evolution can be described by the unitary operator $U = S(H \otimes I)$:

$$|\psi(t+1)
angle = U \ket{\psi(t)} = U^{t+1} \ket{\psi(0)}$$
 .

▲□▶ ▲□▶ ▲□▶ ▲□▶ □ のQで

Let us start the quantum walk from state $|\psi(0)\rangle = |0\rangle \otimes |0\rangle$. If we apply the unitary operator U once, we get

$$|0\rangle\otimes|0\rangle \xrightarrow{H\otimes l} rac{|0
angle+|1
angle}{\sqrt{2}}\otimes|0
angle$$

$$\stackrel{s}{\longrightarrow} rac{1}{\sqrt{2}} (\ket{0} \otimes \ket{1} + \ket{1} \otimes \ket{-1}).$$

Now if we perform a measurement right after the first step, we find the walker at k = 1 w.p. 1/2 and at k = -1 w.p. 1/2. Same as in the classical case.

(日) (四) (日) (日) (日)

However, if we delay measurement, things become quite surprising.

Discrete-time coined quantum walk

 $P[X_{50} = k]$ after measurement, (the figure is from Wikipedia) Blue – Classical Random Walk, Orange – Quantum Walk

It turns out that

for the quantum walk, after measurement: $\sqrt{E[(X_t)^2]} \sim t$, whereas for the classical one: $\sqrt{E[(X_t)^2]} \sim \sqrt{t}$.

Some deficiencies of coined quantum walk:

- The coined quantum walk requires auxiliary degrees of freedom;
- The coined quantum walk can only be generalized to regular graphs;
- No natural definition of hitting times.

There have been developed versions of quantum walk that address the two latter points (Szegedy's model, Portugal's staggered model).

人口 医水黄 医水黄 医水黄素 化甘油

In Szegedy's model, we can define the quantum hitting time as the smallest number of steps T such that

$$rac{1}{T+1}\sum_{t=0}^T || \ket{\psi'(t)} - \ket{\psi(0)} ||^2 \geq 1-rac{m}{n},$$

where m = |M| is the size of the target set.

Theorem (Szegedy) The quantum hitting time is quadratically smaller than the classical expected hitting time.

This provides one more theoretical justification of Grover's search algorithm.

► Given symmetric graph matrices such as adjacency matrix A, Laplacian matrix L = diag(A<u>1</u>) - A, e.g.,

$$a_{ij} = \begin{cases} 1 & \text{if nodes } i \text{ and } j \text{ are linked}, \\ 0 & \text{otherwise.} \end{cases}$$

► Find eigenvalues: λ₁ ≥ λ₂ ≥ ... ≥ λ_n and corresponding eigenvectors: u₁,..., u_n.

Les Misérables network

- A classical problem in graph theory,
- More difficult for large, sparse graphs
- An efficient solution is spectral clustering: Requires knowledge of top eigenvalues and eigenvector graph matrices.

Number of triangles:

- Total number of triangles in a graph: $\frac{1}{6} \sum_{i=1}^{n} |\lambda_i|^3$.
- Number of triangles that a node *m* participated in: $\frac{1}{2} \sum_{i=1} |\lambda_i^3| \mathbf{u}_i(m)$
- Dimensionality reduction, spatial embedding and link prediction: Each node is mapped into a point in R^k space, typically k << n.</p>
- Finding near-cliques: Phenomenon of EigenSpokes in eigenvector-eigenvector scatter plot of the adjacency matrix.

人口 医水黄 医水黄 医水黄素 化甘油

Challenges in classical techniques for distributed implementation:

Power iteration:

$$\mathbf{b}_{\ell+1} = \frac{1}{\|\mathbf{b}_{\ell}\|} \mathbf{A} \mathbf{b}_{\ell} \implies \begin{aligned} \lambda_1 &= \lim_{k \to \infty} \frac{\mathbf{b}_{k+1} \mathbf{b}_k^{\mathsf{T}}}{\|\mathbf{b}_k\|} \\ \mathbf{u}_1 &= \lim_{k \to \infty} \frac{\mathbf{b}_k}{\|\mathbf{b}_k\|} \end{aligned}$$
Drawback: Only principal components; orthonormalization is needed.

Inverse iteration method, Arnoldi-type methods: Drawback: Also require orthonormalization.

Central idea – Complex Power Iterations

- Approach based on Fourier transform of Quantum Walks.
- ► Let $\mathbf{b}_t = e^{i\mathbf{A}t}\mathbf{b}_0$ be a solution of $\frac{\partial}{\partial t}\mathbf{b}_t = i\mathbf{A}\mathbf{b}_t$, Schrödinger equation, describing the dynamics of QW.

From the spectral theorem, we have

$$\frac{1}{2\pi}\int_{-\infty}^{+\infty}e^{i\mathbf{A}t}e^{-it\theta}dt=\sum_{j=1}^{n}\delta_{\lambda_{j}}(\theta)\mathbf{u}_{j}\mathbf{u}_{j}^{\mathsf{T}}$$

Idea of smoothing by Gaussian kernel:

With the help of continuous-time QW on a graph: $|\psi(t)\rangle = e^{i\mathbf{A}t} |\psi(0)\rangle$: $|\psi(t)\rangle$ is a complex amplitude vector $\{\langle i|\psi(t)\rangle, 1 \leq i \leq n\}$ with the probability of finding QW in node *i* at time *t* is $|\langle i|\psi(t)\rangle|^2$.

Practical implementation can be made with either:

- a combination of a splitting chain of polarized gates and quantum Fourier transform; or
- diffusion of complex fluid.
