(Received 28 August 2013; published 19 February 2014)

We study the statistical properties of orientation and rotation dynamics of elliptical tracer particles in two-dimensional, homogeneous, and isotropic turbulence by direct numerical simulations. We consider both the cases in which the turbulent flow is generated by forcing at large and intermediate length scales. We show that the two cases are qualitatively different. For large-scale forcing, the spatial distribution of particle orientations forms large-scale structures, which are absent for intermediate-scale forcing. The alignment with the local directions of the flow is much weaker in the latter case than in the former. For intermediate-scale forcing, the statistics of rotation rates depends weakly on the Reynolds number and on the aspect ratio of particles. In contrast with what is observed in three-dimensional turbulence, in two dimensions the mean-square rotation rate increases as the aspect ratio increases.

The elucidation of the statistical properties of fluid turbulence is a problem of central importance in a variety of areas that include fluid dynamics, nonlinear dynamics, and nonequilibrium statistical mechanics [1–4]. Over the last decade or so, important advances have been made in developing an understanding of the statistical properties of homogeneous, isotropic turbulence in the Lagrangian framework [5–7]. Most of the studies in this framework, whether experimental, theoretical, or numerical, have used spherical or circular tracer particles in three and two dimensions. The study of the dynamics of nonspherical particles in turbulent flows has applications in the simplest models for swimming microorganisms [8], ice crystals in clouds [9], and fibers in the paper industry [10]. Recent work in three-dimensional (3D) turbulent flows [11–17] and in two-dimensional (2D) low-Reynolds-number flows [18,19] has renewed interest in Lagrangian studies with anisotropic particles. We extend these studies to 2D, homogeneous, and isotropic turbulence with elliptical tracer particles. Our study yields several interesting results, which have neither been obtained nor anticipated hitherto. We show that the dynamics of elliptical particles depends significantly on whether the fluid is forced at (A) large or (B) small length scales; the alignment of \mathbf{p} , the unit vector along the semimajor axis of an elliptical particle, and $\nabla \times \boldsymbol{\omega}$, where $\boldsymbol{\omega}$ is the vorticity, is more pronounced in case (A) than in case (B); and the statistics of the particle-rotation rate depends appreciably on the Reynolds number of the flow and the aspect ratio of the particles in case (A) but not in case (B). Moreover, we find important differences between the statistical properties of elliptical tracers in 2D turbulence and their counterparts for ellipsoidal particles in 3D turbulence. In three dimensions, \mathbf{p} exhibits a strong alignment with $\boldsymbol{\omega}$ [12], the mean-square-rotation rate of \mathbf{p} decreases as the aspect ratio of particles increases [13], and the autocorrelation function of \mathbf{p} decays exponentially, with a correlation time increasing as

a function of the Reynolds number [12]. By contrast, in two dimensions, we show that the alignment of \mathbf{p} and $\nabla \times \boldsymbol{\omega}$ is much weaker than its analog in three dimensions, namely, the alignment of \mathbf{p} and $\boldsymbol{\omega}$; in addition, the mean-square-rotation rate of \mathbf{p} increases as the aspect ratio of particles increases. We thus extend significantly what is known about the differences between 2D and 3D turbulence [2,4,20,21].

The 2D, incompressible Navier-Stokes equations can be written in terms of the stream function ψ and the vorticity $\boldsymbol{\omega} = \nabla \times \mathbf{u}(\mathbf{x}, t) \equiv \omega \hat{\mathbf{z}}$, where $\mathbf{u} \equiv (-\partial_y \psi, \partial_x \psi)$ is the fluid velocity at the point \mathbf{x} and time t , and $\hat{\mathbf{z}}$ is the unit normal to the fluid film:

$$D_t \boldsymbol{\omega} = \nu \nabla^2 \boldsymbol{\omega} - \mu \boldsymbol{\omega} + \mathbf{f}_\omega; \quad \nabla^2 \psi = \omega. \quad (1)$$

Here $D_t \equiv \partial_t + \mathbf{u} \cdot \nabla$, the uniform solvent density $\rho = 1$, μ is the coefficient of friction (which is always present in experimental fluid films [22]), and ν is the kinematic viscosity of the fluid. We use a zero-mean, Gaussian stochastic forcing with $\langle \tilde{\mathbf{f}}_\omega(\mathbf{k}) \tilde{\mathbf{f}}_\omega(\mathbf{k}') \rangle = A(\mathbf{k}) \delta(\mathbf{k} + \mathbf{k}')$, where $A(\mathbf{k}) = f_{\text{inj}}$ if $|\mathbf{k}| = k_{\text{inj}}$ and zero otherwise, the tilde denotes a spatial Fourier transform, and k_{inj} is the length of the energy-injection wave vector. The configuration of an elliptical particle is given by the position of its center of mass, \mathbf{x}_c , and by the axial unit vector $\mathbf{p} = (\cos \theta, \sin \theta)$ that specifies the orientation of the semimajor axis with respect to a fixed direction. The elliptical particles we consider are neutrally buoyant, of uniform composition, and much smaller than the viscous dissipation scale, so the velocity gradient is uniform over the size of a particle. In addition, we study suspensions that are sufficiently dilute for hydrodynamic particle-particle interactions to be disregarded. Under the above assumptions, \mathbf{x}_c satisfies

$$\dot{\mathbf{x}}_c = \mathbf{u}(\mathbf{x}_c(t), t); \quad (2)$$

and the time evolution of the orientation is given by the Jeffery equation [23], which reduces in a 2D, incompressible flow to the following one for the angle θ :

$$\dot{\theta} = \frac{1}{2} \omega + \gamma(\alpha) [\sin(2\theta) S_{11} - \cos(2\theta) S_{12}], \quad (3)$$

TABLE I. The parameters for our DNS runs. Here, $\eta \equiv (\nu^3/\varepsilon)^{1/4}$ is the dissipation scale, $\lambda \equiv \sqrt{\nu\mathcal{E}/\varepsilon}$ is the Taylor-microscale, $\text{Re}_\lambda \equiv u_{\text{rms}}\lambda/\nu$ is the Taylor-microscale Reynolds number, $T_{\text{eddy}} \equiv \sum_k \frac{\langle E(k)/k \rangle}{E(k)}/u_{\text{rms}}$ is the eddy-turnover time, and $\tau_\eta \equiv \sqrt{\nu/\varepsilon}$ is the Kolmogorov time scale, where $\mathcal{E} \equiv \langle \frac{1}{2} |u(x,t)|^2 \rangle_{x,t}$, where $\langle \cdot \rangle_{x,t}$ denotes a space-time average, is the total kinetic energy of the flow, u_{rms} is the root-mean-square velocity, ε is the kinetic-energy dissipation rate, and $E(k) \equiv \sum_{k-1/2 < k' \leq k+1/2} k'^2 \langle |\tilde{\psi}(k',t)|^2 \rangle_t$, where $\langle \cdot \rangle_t$ indicates a time average over the statistically steady state, is the fluid-energy spectrum. The Lagrangian correlation times of S_{11} , S_{12} , and ω are defined as $\tau_{S_{11}} \equiv \langle S_{11}^2 \rangle^{-1} \int_0^\infty \langle S_{11}(t)S_{11}(0) \rangle dt$, $\tau_{S_{12}} \equiv \langle S_{12}^2 \rangle^{-1} \int_0^\infty \langle S_{12}(t)S_{12}(0) \rangle dt$, and $\tau_\omega \equiv \langle \omega^2 \rangle^{-1} \int_0^\infty \langle \omega(t)\omega(0) \rangle dt$, respectively.

where $S_{ij} = (\partial_i u_j + \partial_j u_i)/2$ are the components of the rate-of-strain tensor evaluated at \mathbf{x}_c , $\gamma(\alpha) \equiv (\alpha^2 - 1)/(\alpha^2 + 1)$, and α is the ratio of the lengths of the semimajor and semiminor axes of the elliptical particle; γ varies from 0 (circular disks) to 1 (thin rods).

Our direct numerical simulation (DNS) of Eqs. (1)–(3) uses periodic boundary conditions over a square domain with side $L = 2\pi$, a pseudospectral method [24] with $N^2 = 2048^2$ collocation points, the 2/3 dealiasing rule, and, for the time evolution, a second-order, exponential-time-differencing Runge-Kutta method [25,26]. For the integration of Eq. (2), we use an Euler scheme, because, in one time step δt , a tracer particle crosses roughly one-tenth of a grid spacing. At off-lattice points, we evaluate the particle velocity from the Eulerian velocity field by using a bilinear-interpolation scheme [27]. Finally, we integrate Eq. (3) by using an Euler scheme, with the same time step as for Eq. (2); and, at $t = 0$, the orientation angles are uniformly distributed over $[0, 2\pi]$. We track $N_p = 10^4$ particles over time to obtain the statistics of particle alignment and rotation for 12 different values of $0 < \gamma \leq 1$. We collect data for averages only when our system has reached a nonequilibrium statistically steady state, i.e., for $t > 20T_{\text{eddy}}$, where T_{eddy} is the integral-scale eddy-turnover time of the flow. The parameters used in our simulations are given in Table I. Our study consists of two sets of simulations (A) and (B) at comparable values of Re_λ , the Taylor-microscale Reynolds numbers. In (A), the flow is forced at small k_{inj} (i.e., a large length scale); in (B), it is forced at an intermediate value of k_{inj} (i.e., an intermediate length scale); even in case (B) k_{inj} is small enough that the energy spectrum displays both a part with an inverse-energy cascade and a part with a forward cascade of enstrophy. We have also performed simulations at a lower resolution ($N = 1024$) and obtained similar results, so our study does not suffer from finite-resolution effects.

In Fig. 1(a), we show a pseudocolor plot of ω for case (A) at a representative time in the statistically steady state; Fig. 1(b) shows the positions and the orientations of particles at the same time; an elliptical particle is represented here by a black line whose center indicates \mathbf{x}_c and whose orientation is that of \mathbf{p} . Analogous plots for case (B) are given in Figs. 1(c) and 1(d). Figure 1 suggests that the particle dynamics is qualitatively different in cases (A) and (B). In particular, in the former case, the orientation of particles is such that we see large-scale structures, which are absent in the latter case. To quantify this

behavior, we study the statistics of the alignment of particles with the local directions of the flow.

The curl of the vorticity is tangent to the isolines of ω ; a strong alignment between \mathbf{p} and $\nabla \times \boldsymbol{\omega}$ would thus indicate a significant correlation between the spatial distribution of particle orientations and the vorticity field. Figure 2 shows the probability density function (PDF) of the angle χ between \mathbf{p} and $\nabla \times \boldsymbol{\omega}$. In case (A), \mathbf{p} tends to align with $\nabla \times \boldsymbol{\omega}$, but the alignment is not very strong. A careful inspection of Fig. 1 shows indeed that the spatial distribution of particle orientations does not closely reproduce the isolines of vorticity. Moreover, the alignment weakens as γ decreases and Re_λ increases (Fig. 2). In case (B), the PDF of χ depends very weakly on χ ; i.e., the elliptical tracers do not exhibit a definite preferential orientation with respect to $\nabla \times \boldsymbol{\omega}$. We observe this behavior for all the values of Re_λ considered in Fig. 2.

An examination of the statistics of χ shows the first, remarkable difference between the dynamics of nonspherical

FIG. 1. (Color online) (a) Pseudocolor plot of ω at $t = 17.5$ for run A3; (b) particle positions and orientations at $t = 17.5$ for run A3 and $\gamma = 1$; (c) pseudocolor plot of ω at $t = 17.5$ for run B3; (d) particle positions and orientations at $t = 17.5$ for run B3 and $\gamma = 1$. The number of particles shown in (b) and (d) is 2×10^3 . For the spatiotemporal evolution of these plots see Ref. [29].

FIG. 2. (Color online) PDFs of the angle between \mathbf{p} and $\nabla \times \boldsymbol{\omega}$. Left: Run A1 (solid, blue curve), run A2 (dashed, red curve), and run A3 (dot-dashed, black curve) for $\gamma = 1$. The inset shows the same PDF for run A3 and different values of γ (from top to bottom, $\gamma = 1, 3/4, 1/2,$ and $1/4$). Right: Run B1 (solid, blue curve), run B2 (dashed, red curve), and run B3 (dot-dashed, black curve) for $\gamma = 1$. The inset shows the same PDF for run B3 and different values of γ (from top to bottom, $\gamma = 1, 3/4, 1/2,$ and $1/4$).

tracers in three dimensions and that of elliptical particles in two dimensions. In three dimensions, the tracer particles align strongly with $\boldsymbol{\omega}$ [12]. This behavior has been explained in Ref. [12] by arguing that, if viscosity is disregarded, the equation describing the Lagrangian evolution of $\boldsymbol{\omega}/|\boldsymbol{\omega}|$ is equivalent to the evolution equation for the axial unit vector of a thin rod. In two dimensions, an analogous equivalence exists, because $(\nabla \times \boldsymbol{\omega})/|\nabla \times \boldsymbol{\omega}|$ satisfies the Jeffery equation with $\gamma = 1$ (provided that $\nu = 0$). In two dimensions, this formal equivalence does not yield a strong alignment between \mathbf{p} and $\nabla \times \boldsymbol{\omega}$ because the effect of the viscosity on $\nabla \times \boldsymbol{\omega}$ in two dimensions is more important than its effect on $\boldsymbol{\omega}$ in three dimensions. The aforementioned equivalence also explains why the alignment of particles with $\nabla \times \boldsymbol{\omega}$ becomes weaker as their aspect ratio decreases; and indeed the evolution equation for \mathbf{p} increasingly deviates from that for $(\nabla \times \boldsymbol{\omega})/|\nabla \times \boldsymbol{\omega}|$. The decrease of the probability of alignment with increasing Re_λ is, on the contrary, attributable to the increase of the fluctuations of the components of $\nabla \mathbf{u}$.

The eigenvectors of S form a Lagrangian orthogonal frame of reference. In Fig. 3, we show the PDF of the angle β between \mathbf{p} and the eigenvector \mathbf{e}_1 , associated with the positive eigenvalue of S . Particles tend to align with \mathbf{e}_1 , but the alignment is weaker in case (B) than in case (A). The alignment becomes weaker as γ decreases, because the contribution of

FIG. 3. (Color online) PDFs of the angle β between \mathbf{p} and \mathbf{e}_1 for $\gamma = 1$ and different Re_λ in case (A) (left) and in case (B) (right). The insets show the PDF of β for different values of γ for runs A3 (left) and B3 (right). The color code is the same as in Fig. 2.

FIG. 4. (Color online) Single-time two-point correlation function of M as a function of the space separation rescaled by the correlation length. Left: Run A1 (solid, blue curve), run A2 (dashed, red curve), and run A3 (dot-dashed, black curve) for $\gamma = 1$. Right: Run B1 (solid, blue curve), run B2 (dashed, red curve), run B3 (dot-dashed, black curve) for $\gamma = 1$. The insets show the correlation length as a function of γ ; the color code is the same as in the main plots.

S to the evolution of \mathbf{p} diminishes [see Eq. (3)]. The tendency of particles to align with \mathbf{e}_1 diminishes as Re_λ increases, i.e., as turbulent fluctuations are enhanced. The moderate degree of alignment, shown in Fig. 3, is comparable with that found for rods in 2D, low-Reynolds-number flows [18] and in 3D, homogeneous, isotropic turbulence [12].

We have calculated the conditional PDFs of the alignment of particles conditioned on the sign of the Okubo-Weiss parameter [26,28], which distinguishes between vortical and extensional regions of the flow; the conditional PDFs do not deviate from their unconditional counterparts [29].

To quantify the spatial distribution of particle orientations, we define the correlation function $\Gamma(r) = [\langle M(\mathbf{r}, t)M(\mathbf{0}, t) \rangle - \langle M(\mathbf{r}, t) \rangle \langle M(\mathbf{0}, t) \rangle] / \langle M^2 \rangle$, where $M(\mathbf{r}, t) \equiv [2 \cos^2 \theta(\mathbf{r}, t) - 1]$ is the local nematic order parameter in two dimensions [30] and $\langle \cdot \rangle$ denotes an average over time and over the tracer particles. The function $\Gamma(r)$ is shown in Fig. 4 for different values of Re_λ . In both cases (A) and (B), the shape of $\Gamma(r)$ depends only weakly on Re_λ . However, in case (A), the order parameter of rods is correlated up to distances of the order of 5% of L and is anticorrelated at large r ; in case (B), $\Gamma(r)$ decays exponentially to zero. These behaviors are in accordance with the spatial distributions of orientations shown in Fig. 1. Furthermore, in case (A), the correlation length $L_\Gamma = [\int_0^\pi \Gamma(r) dr] / \Gamma(0)$ depends weakly on Re_λ , because the value of L_Γ is determined principally by k_{inj} ; in case (B), the size of large-scale flow structures increases with increasing Re_λ [31]; hence, L_Γ increases accordingly. In both cases, L_Γ is obviously an increasing function of γ .

Let us now examine the temporal autocorrelation function of \mathbf{p} . In both cases (A) and (B), $C(t) = \langle \mathbf{p}(t) \cdot \mathbf{p}(0) \rangle$ decays exponentially to zero (Fig. 5), but the correlation time $\tau_c = \int_0^\infty C(t) dt$ is much shorter in the former case. The ratio τ_c / τ_η increases as a function of both Re_λ and γ ; this behavior is similar to that observed in 3D turbulence, where the orientational dynamics of spheres decorrelates faster than that of rods [12].

Figure 6 shows the PDFs of the rotation rate $\dot{\theta}$ of particles for different values of Re_λ (for the analogous PDFs at fixed Re_λ and different γ ; see [29]). Very large fluctuations characterize the statistics of $\dot{\theta}$, as has been observed in 3D turbulence [13]. However, the probability of large fluctuations increases with

FIG. 5. (Color online) Autocorrelation function of \mathbf{p} as a function of the time separation rescaled by τ_η for different Re_λ in case (A) (left) and in case (B) (right). The insets show the correlation time rescaled by τ_η as a function of γ for different Re_λ . The color codes are the same as in Fig. 4.

increasing γ and Re_λ in case (A), whereas it depends weakly on γ and Re_λ in case (B). The main difference between 2D and 3D cases is the dependence of the mean-squared-rotation rate $\langle \dot{\theta}^2 \rangle$ upon γ . In three dimensions, $\langle \dot{\theta}^2 \rangle$ decreases as γ increases and is thus smaller for rods than for spheres [13]. The reason for this behavior is that the tendency to align with $\boldsymbol{\omega}$ is stronger for elongated particles [12,13] than for spheres. In two dimensions, such an alignment cannot take place and $\langle \dot{\theta}^2 \rangle$ increases as γ increases.

We have examined the statistics of the orientational and rotational dynamics of elliptical tracers in 2D, homogeneous, and isotropic turbulence. By considering two sets of simulations with different k_{inj} , we have shown that these properties depend on the scale at which the turbulent flow is generated. In the small- k_{inj} case, the spatial correlation of the nematic order parameter indicates the existence of large-scale structures in the spatial distribution of \mathbf{p} , which are absent in the intermediate- k_{inj} case. Moreover, the probability of \mathbf{p} being aligned with $\nabla \times \boldsymbol{\omega}$ or \mathbf{e}_1 is much lower for intermediate k_{inj} than for small k_{inj} . These differences can be explained by noting that the dynamics of fluid particles is different in the

FIG. 6. (Color online) PDFs of θ rescaled by $\dot{\theta}_{rms} = \sqrt{\langle \dot{\theta}^2 \rangle}$ for $\gamma = 1$ and different Re_λ in case (A) (left) and in case (B) (right). The insets show the mean-square rotation rate multiplied by τ_η^2 as a function of γ . The color codes are the same as in Fig. 4.

direct- and inverse-cascade regimes [32,33], and hence the Lagrangian statistics of $\nabla \mathbf{u}$ depends on k_{inj} (see, e.g., τ_{S11} , τ_{S12} , and τ_ω given in Table I, as well as the Lagrangian autocorrelation functions of the components of $\nabla \mathbf{u}$ reported in [29]). Our study sheds new light on the qualitative differences between 2D and 3D homogeneous, isotropic fluid turbulence. These differences lead to a weaker alignment between \mathbf{p} and $\nabla \times \boldsymbol{\omega}$ in two dimensions as compared to the alignment between \mathbf{p} and $\boldsymbol{\omega}$ in three dimensions and to a different dependence of $\langle \dot{\theta}^2 \rangle$ upon γ (as γ increases, $\langle \dot{\theta}^2 \rangle$ increases in two dimensions but decreases in three dimensions). We hope our comprehensive study of the statistical properties of elliptical tracer particles in 2D, homogeneous, and isotropic turbulent fluid flows will stimulate experimental studies of such particles.
